The direction of others' eye gaze has important influences on how we perceive their emotional expressions. Here, we examined differences in neural activation to direct- versus averted-gaze fear faces as a function of culture of the participant (Japanese versus US Caucasian), culture of the stimulus face (Japanese versus US Caucasian), and the relation between the two. We employed a previously validated paradigm to examine differences in neural activation in response to rapidly presented direct- versus averted-fear expressions, finding clear evidence for a culturally determined role of gaze in the processing of fear. Greater neural responsivity was apparent to averted- versus direct-gaze fear in several regions related to face and emotion processing, including bilateral amygdalae, when posed on same-culture faces, whereas greater response to direct- versus averted-gaze fear was apparent in these same regions when posed on other-culture faces. We also found preliminary evidence for intercultural variation including differential responses across participants to Japanese versus US Caucasian stimuli, and to a lesser degree differences in how Japanese and US Caucasian participants responded to these stimuli. These findings reveal a meaningful role of culture in the processing of eye gaze and emotion, and highlight their interactive influences in neural processing.

INTRODUCTION

Dating back to Darwin's seminal book, *On the expression of the emotions in man and animals* (1872/1965), cross-cultural research has served a critical role in establishing the universality of how we express and recognize basic emotional displays. Following this tradition, contemporary research efforts by Paul Ekman and colleagues employed cross-cultural methodology to examine the neurocultural theory of emotion (Ekman, 1972), in which they proposed that a *universal affect program* underlies the experience and expression of certain basic emotions (i.e. anger, fear, sad, happy, disgust, surprise; see Ekman and Friesen, 1971). According to this theory, basic emotional displays are universal and thus expressed and recognized uniformly across all cultures.

In a recent meta-analysis, it became apparent that measurable intracultural advantages also exist in basic emotion recognition (Elfenbein and Ambady, 2002). Elfenbein and Ambady (2003a; 2003b) posited the existence of a *specific affect program*, one that exerts subtle variation, like accents,

on both the expression and perception of otherwise universal emotional displays (see also Marsh *et al.*, 2003). In addition to such nuanced influences, there exist explicitly learned display rules (Ekman, 1972) and decoding rules (Matsumoto, 1989) that vary across cultures. These rules motivate individuals to override standard universal responses in overt attempts to, for example, mask, neutralize, or emphasize expressions according to what is deemed culturally appropriate. Of particular relevance to the current inquiry are cultural rules governing emotional expression and eye gaze behaviors.

Culture and emotion communication

In one example of culturally learned display rules, male Japanese participants were found to smile more often than male US Caucasian participants when viewing unpleasant film clips in the presence of others (Friesen, 1972; cited in Matsumoto, 2001). In Japanese society, overt displays of many negative emotions tend to be discouraged and thus smiling behavior in this context was considered an attempt to mask negative emotion. In US culture, however, overt displays of many negative emotions are often considered appropriate (Matsumoto, 1990). Such norms in turn influence inferences people make when reading the emotional expressions of others. For instance, when the norm of a culture is to express overt emotion, such as in the USA, less intensity is read into such displays, whereas when the

norm is to attenuate overt expression, such as in Japan, more intensity is read into these displays (Matsumoto, Kasri, and Kooken, 1999).

Evidence for cultural variation in emotion processing at the neural level remains limited. One study examined such differences, reporting distinct regions of activation between Caucasian and Japanese participants when viewing fearful expressions (Moriguchi *et al.*, 2005). Specifically, when viewing fear faces, US Caucasian participants recruited more posterior cingulate, amygdala and supplementary motor cortex as compared to Japanese participants, who recruited more inferior frontal cortex, premotor cortex and insula. These findings were interpreted as reflecting different culturally learned styles for decoding emotion. In a more recent study, the interaction of stimulus and observer culture was explored in Japanese and US Caucasian participants. Specifically, evidence was found for cultural tuning in neural responses to fear expressions (Chiao *et al.*, 2008), with greater activation in the bilateral amygdalae in response to viewing same- compared to other-culture fear expressions (this effect was consistent across both cultural groups; see Adams *et al.*, in press, for similar intracultural effect in bilateral posterior superior temporal sulci during complex mental state decoding). Chiao *et al.* reported similar effects in the left hippocampus, right superior temporal sulcus, right caudate, left superior frontal gyrus, right parahippocampal gyrus and right middle frontal gyrus.

Culture and eye gaze behavior

As with expression, eye gaze represents another nonverbal behavior with great social significance. Although eye gaze appears to be a universally important social cue, it can exert different meanings across cultures. Argyle and Cook (1976), for instance, suggested that in Western cultures, eye gaze is generally seen as a sign of respect. A failure to make eye contact may therefore be interpreted as suspicious. In East Asian cultures, making eye contact can be impolite and seen as threatening under certain circumstances, whereas averted eye gaze, especially downward shifts, can be seen as respectful (Knapp and Hall, 2002). Consequently, US Caucasian participants tend to look a same-culture experimenter in the eye when answering a question and Japanese participants tend to look away from a same-culture experimenter (McCarthy *et al.*, 2006).

To date, the influence of culture on neural responses to gaze information has not been examined. However, one study examined the influence of gaze on responses to viewing same- versus other-race faces (Richeson *et al.*, 2008). In this study, when contrasting responses in Caucasian participants to direct- versus averted-gaze Black faces, more right amygdala activation was evident, as well as bilateral insula, left supramarginal gyrus, right hippocampus, right middle frontal gyrus, left inferior occipital gyrus, right precentral gyrus, and medial orbital gyrus. Similar responses were not apparent when viewing White faces, leading the authors to

conclude that the threatening, approach-oriented signal stereotypically ascribed to Black faces was compounded by direct gaze (see also Adams and Kleck, 2003, 2005; Ambady and Adams, in press, for rationale of compound social cues).

Eye gaze and emotion

Eye gaze also affects the perception of emotional expression. Using speeded reaction time tasks and self-reported perception of emotional intensity, Adams and Kleck (2003, 2005) found that direct relative to averted gaze affected perceptions of approach-oriented emotional facial expressions (e.g. anger and joy) by facilitating speed of processing, increasing recognition accuracy, and augmenting perceived intensity. Averted relative to direct gaze, on the other hand, exerted a similar influence on the perception of avoidance-oriented emotions (e.g. fear and sadness). Such interactive influences of gaze and emotion perception has since been replicated and extended by Sander *et al.* (2007) using dynamic threat displays, by Hess, Adams, and Kleck (2007) examining reactive responses to displays in observers, and by Graham and LaBar (2005; see also Bindeman *et al.*, 2008) who demonstrated that the relative salience of eye gaze and emotion moderates such interactive influences.

Similarly, emotional expression has been found to influence the processing of eye gaze information. Studying individuals with high anxiety, for instance, Fox *et al.* (2008) found that fear expressions facilitated reflexive orienting to averted eyes, whereas anger facilitated attention capture to the face. Similarly, using a speeded reaction time task, Adams and Franklin (2009) found that facial expressions of anger facilitated the recognition of direct eye gaze and facial expressions of fear facilitated the recognition of averted eye gaze. Finally, another recent study revealed that observers tend to misperceive eye gaze as looking directly at them more often when presented on happy and angry faces as compared to neutral and fearful faces (Lobmaier *et al.*, 2008).

The interaction between eye gaze and emotion is also apparent at the neural level. Adams *et al.* (2003) reported evidence for an interaction between eye gaze and emotion processing such that the left amygdala responded more when participants viewed ambiguous threat-gaze pairings (direct-gaze fear and averted-gaze anger) compared to congruent threat-gaze pairings (averted-gaze fear and direct-gaze anger). This finding fits with previously reported patterns of amygdala activation to fear and anger faces that were presented with only direct gaze (e.g. Whalen *et al.*, 2001). To explain these previous results, Whalen (1998; see also Davis and Whalen, 2001) proposed that the amygdala may be instrumental in processing threat-related ambiguity, and thus the level of response may be directly proportional to the level of ambiguity surrounding the source of a threat. Adams *et al.*'s findings corroborate this hypothesis, replicating the original pattern found by Whalen and his colleagues in direct-gaze faces (i.e. greater amygdala activation to

fearful faces than to angry faces), while revealing the reverse pattern for averted-gaze faces (i.e. greater amygdala activation to angry faces than to fearful faces).

Despite evidence for amygdala responses to threat-ambiguity as described above, there also exists recent evidence for greater amygdala responsivity to congruent versus ambiguous threat-gaze pairs. In one study, which presented predominantly US Caucasian faces to US Caucasian perceivers, greater amygdala response was found to averted-relative to direct-gaze fear faces (Hadjikhani *et al.*, 2008), as well as greater superior temporal sulcus, intraparietal sulcus, fusiform, inferior occipital gyrus, hypothalamus, pallidum, visual area MT, premotor/motor cortex, caudate, somatosensory cortex, and anterior fusiform. Similarly, in a study presenting Japanese faces to Japanese perceivers, greater amygdala activation was found in response to peripherally presented anger expressions looking in toward a fixation cross (i.e. oriented inward toward the observer) relative when looking away from a fixation cross (i.e. oriented outward away from the observer; Sato *et al.*, 2004). Thus, whereas Adams *et al.*'s (2003) findings seem to implicate a top-down process involved in deciphering ambiguity, these more recent findings (Sato *et al.*, 2004; Hadjikhani *et al.*, 2008) seem to indicate a more reflexive alerting response to salient threat-gaze combinations. Moderators of these opposing effects remain undetermined, but variations in stimulus clarity and temporal factors are likely candidates (see also Mogg, Garner, and Bradley, 2007). For the purposes of the current examination, in which we focused on examining cross-cultural influences on the role of gaze and in early threat perception, we employed a modified version of Hadjikhani *et al.*'s paradigm, using rapid (300 ms) presentations, as opposed to longer presentations previously employed by our own research team (i.e. 2 s; Adams *et al.*, 2003).

The current study

The aim of the current study was to extend previous research examining the role of gaze in emotion processing by focusing on the impact of culture on the role of gaze in basic fear perception. Specifically, we were interested in examining responses to rapidly presented fear expressions, following Hadjikhani *et al.*'s (2008) findings of greater amygdala responsivity to clear versus ambiguous fear-gaze pairings when using short exposures. Given the literature reviewed above, our primary predictions were that same-culture faces would yield greater amygdala activation for averted- versus direct-gaze fear. In accordance with Chiao *et al.*'s (2008) finding for culturally tuned amygdala responses to fear expressions, we predicted that this effect would be greater in response to same- versus other-culture faces. Finally, considering recent evidence for greater amygdala responses to other-race faces when displaying direct- versus averted-gaze (Richeson *et al.*, 2008), we were also able to explore whether similar group differences might extend to cultural group

memberships as well, which predicts greater direct- relative to averted-gaze amygdala responses to other-culture faces. Notably, these predictions all represent intracultural influences in which similar responses across cultures would vary as a function of the relationship between the stimulus culture and the participant culture. Given evidence for explicit differences in cultural display rules regarding emotion and gaze behavior, we were also interested in exploring potential intercultural variation in neural responses to emotional expression and eye gaze behavior.

METHOD

Participants

Thirty-four participants were recruited using online postings or paper advertisements. Sixteen native Japanese students (eight women) and 18 Caucasian students (nine women) participated in the study for financial compensation. The Japanese students were visiting the USA as part of a university summer English language program. None of these students had spent more than a month in the USA prior to participating in this study. All participants were right handed, had normal or corrected-to-normal vision, and had no known medical, neurological, or psychiatric history. Two Japanese participants (one man, one woman) were dropped from the analysis because of excessive movement during the trials or anatomical features that impeded normalization into standard brain space.

Stimuli

We selected eight images (four women, four men) of Caucasian models displaying fearful faces from the Pictures of Facial Affect (Ekman and Friesen, 1978). These faces were ones used by Adams *et al.* (2003), and had been previously shown using a speeded reaction time paradigm to yield faster recognition for averted versus direct gaze fear when viewed by US Caucasian participants. In each of these images, we digitally altered eye gaze using Adobe Photoshop to generate faces with direct- and laterally averted (left and right) gaze. We selected Japanese faces from a larger set constructed at Kyoto University (Yoshikawa, 2009), which were similarly digitally manipulated to create direct and averted eye gaze. In order to match these faces with the Caucasian set, we chose eight models (four women, four men) that similarly yielded faster responding to averted than direct gaze fear when viewed by Japanese participants.

Procedure

As noted earlier, we adopted a version of the paradigm used by Hadjikhani *et al.* (2008), which consisted of two runs of passive viewing in an ABA block design alternating between direct and averted gaze fear faces showing either Japanese or Caucasian individuals across four block types (Caucasian-Averted, Caucasian-Direct, Japanese-Averted, Japanese-Direct). Each block type was repeated four times to yield 16 blocks per run. The culture of the faces alternated

every eight blocks, and was counterbalanced across runs. The order of runs was also counterbalanced across participants. Within each block, sixteen faces were displayed for 300 ms, with a 1200 ms fixation cross displayed between stimuli, totaling 24 s. Each run lasted 6 min and 24 s.

fMRI data analysis

fMRI scanning employed a 3-T Siemens Tim Trio scanner with a standard 12 channel headcoil for data acquisition. Scanning consisted of two experimental functional runs and a T_1 -weighted anatomical scan collected for coregistration and normalization. Functional scans consisted of 192 dynamic whole-brain T_2^* weighted images collected in an oblique axial orientation (TR 2s, TE 30ms, 90° flip angle, voxel size, $3.125 \times 3.125 \times 5$ mm, 32 interleaved slices, 192 volumes, 5 mm slice thickness with 1 mm slice gap). High-resolution T_1 -weighted (MP-RAGE, 128 sagittal slices 1.33 mm thick, 256×256 matrix) anatomical images were collected for each participant for coregistration with the participants' functional data and display of individual activations. Foam padding around the head was used to minimize head movement. Images were viewed using a back-projection system.

Data were pre-processed and analyzed using SPM5 software. Images were realigned to the first functional image using a six-parameter rigid rotation. Each participant's anatomical image was coregistered to a mean image of each participant's functional images. Anatomical images were normalized according to a T_1 template image using a standard space defined by the Montreal Neurological Institute (MNI) and these normalization parameters were applied to the functional images, in order to allow for group comparisons. Functional images were then smoothed using an 8 mm FWHM Gaussian kernel.

Contrasts were initially estimated using a fixed effects model within each subject. Stimulus conditions were modeled as delayed boxcar functions convolved with a standard hemodynamic response function. Low frequency signal components less than 0.007 Hz were filtered out using a high-pass filter. To make population inferences, contrast images from each subject were then entered into a mixed-effects model representing summary measures of subject responses. Statistical comparisons were conducted using a mass-univariate GLM approach comparing blocks of direct eye gaze with blocks of averted eye gaze.

For the whole-brain analysis we employed a set threshold of $P < 0.001$ (voxelwise), uncorrected, with an extent-threshold of six voxels. First, we computed a voxel-wise 2 (culture of participant) \times 2 (culture of face) mixed effects analysis of variance (ANOVA). We extracted parameter estimates (beta values) for the peaks of each cluster defined by this analysis for each treatment condition to inspect the nature and direction of the main effects and the interaction effects found (Table 1). Since each eye gaze condition served as baseline for the other using this paradigm,

the dependent variable of interest was computed as direct minus averted gaze, with positive BOLD signal thereby indicating more activation to direct gaze and negative to averted gaze.

Based on our *a priori* hypotheses we also ran a region of interest analysis on bilateral amygdalae. To do this, we first extracted mean beta values from the entire anatomically defined region of interest using the AAL atlas (Tzourio-Mazoyer *et al.*, 2002) and the WFU Pickatlas (Maldjian, Laurienti, Burdette, and Kraft, 2002) and submitted these to a subject-wise 2 (laterality: left versus right) by 2 (culture of participant) by 2 (culture of stimulus) mixed factorial ANOVA. We then conducted single-sample *t*-tests (subject-wise) within each treatment condition on the mean beta values extracted from each cluster that survived a threshold of $P < 0.01$ (voxelwise), uncorrected, extent-threshold of five voxels (as in Demos *et al.*, 2008) in order to explicate the nature and direction of these interaction effects. For illustration purposes, all group contrast images were overlaid onto a representative T_1 template anatomical image using MRIcron (<http://www.sph.sc.edu/comd/rorden/mricron.html>).

RESULTS

Whole-brain analysis

We computed a 2 (culture of participant) \times 2 (culture of stimulus) mixed effects analysis of variance (ANOVA), which yielded main effects of culture of participant and culture of stimulus, and an interaction between the two (Figure 1). In order to interpret the direction of these effects, we extracted peak beta values for all significant clusters and have displayed these by treatment condition (Table 1).

Only one significant cluster, the right angular gyrus, was revealed in the main effect of participant culture. Inspection of the peak beta values for each treatment condition shows this effect was driven largely by relatively greater activation to direct versus averted gaze in Japanese participants and averted versus direct gaze in US Caucasian participants viewing fear faces (Table 1, top panel). Several regions were revealed in the main effect of stimulus culture including bilateral inferior temporal gyri, left cerebellum, left lateral occipital gyrus, bilateral angular gyri extending into the intraparietal sulcus, and bilateral fusiform gyri. Upon inspection of these peak beta values, all showed similar patterns of activation. Japanese stimuli tended to elicit greater activation for direct- versus averted-gaze fear faces, whereas US Caucasian faces tended to elicit greater activation for averted- versus direct-gaze fear faces (Table 1, middle panel).

For the interaction between gaze and emotion, significant clusters included bilateral thalamus, bilateral cerebellum, bilateral fusiform, left insula, left ventrolateral prefrontal cortex, left inferior frontal gyrus, left dorsolateral prefrontal cortex, right midbrain, and right parahippocampal gyrus extending into the right amygdala. Inspection of the peak

Fig. 1 (A) Top half of figure depicts global activations associated with main effects and interaction at $P < 0.001$, uncorrected, superimposed on the rendered brain from four perspectives, top, bottom, left, and right. (B) Bottom half of figure depicts activation surviving a threshold of $P < 0.01$, uncorrected within the anatomically specified region of left and right amygdalae, and graphical representations of the mean beta values associated with each treatment condition extracted from these clusters (top left and right) as well as from the mean of all voxels within the bilateral amygdalae (bottom center). The dependent variable was computed as a contrast between direct versus averted gaze perception, such that positive scores represent more activation to direct relative to averted fear, and vice versa for negative scores.

beta values for these regions showed similar patterns of activation across stimulus conditions reflecting relatively greater activation to averted- versus direct-gaze fear for same-culture faces and greater activation to direct- versus averted-gaze fear for other-culture faces (Table 1, bottom panel).

Region of interest analysis

As indicated in the whole-brain voxelwise analysis, there was a cluster of parahippocampal gyrus extending into the right amygdala apparent for the interaction of stimulus and participant culture. In order to isolate and examine amygdala activation specifically, given that it was our primary region

Regions reported posterior to anterior (height: $P < 0.001$, uncorrected; extent: six voxels). Positive beta values indicate greater activation to direct minus averted gaze fear, negative beta values indicate greater activation to averted minus direct gaze fear.

^aRelated studies showing same general regions of activation (without differentiating laterality): (1) Chiao *et al.* (2008), (2) Hadjikhani *et al.* (2008), (3) Moriguchi *et al.* (2005), (4) Richeson *et al.* (2008) and (5) Sato *et al.* (2004).

of interest, we extracted beta values from all voxels within the anatomically defined region of bilateral amygdalae and submitted these to a 2 (laterality: left versus right) by 2 (culture of stimulus: Japanese versus US Caucasian) by 2 (culture of observer: Japanese versus US Caucasian) ANOVA (subject-wise). This analysis revealed only the predicted two-way interaction between culture of stimulus and culture of participant, $F(1, 30) = 5.55$, $P = 0.025$.

In order to examine this interaction more closely, we extracted mean beta values for clusters within the anatomically defined region that survived a threshold of $P < 0.01$ (voxel-wise), uncorrected, extent-threshold: 5 voxels (Demos *et al.*, 2008). At this threshold, clusters in both the left ($x = -28$, $y = -4$, $z = -12$; peak voxel, $P < 0.005$) and right ($x = 30$, $y = -6$, $z = -12$; peak voxel, $P < 0.001$) amygdalae were apparent (bottom Figure 1). We then submitted these mean beta values to one sample *t*-tests comparisons (subject-wise) within each treatment condition to explicate the direction and nature of the interaction. These

comparisons revealed relatively greater activation to direct-versus averted-gaze fear faces in both cultural groups, when viewing *other*-culture faces in both the left and right amygdalae (t 's > 2.3 , P 's < 0.05 , two-tailed). Further, US Caucasian participants showed significantly greater activation to averted- versus direct-gaze fear when viewing *same*-culture fear expressions in the right amygdala [$t(17) = 2.21$, $P < 0.05$, two-tailed], a pattern that was evident but not significant in the left amygdala [$t(17) = 1.58$, $P = 0.16$]. Japanese participants showed no significant differences in either the right or left amygdala when viewing direct versus averted same-culture faces.

DISCUSSION

The current study revealed the predicted interaction between culture of participant and culture of stimulus in a number of regions involving face, gaze and emotion processing, including the bilateral fusiform gyri, left posterior cingulate, bilateral thalamus, left insula, right caudate, left inferior frontal

gyrus, and left ventro- and dorsolateral prefrontal cortices. Helping explain the interaction effects within these regions was the relative increase in activation to direct- versus averted-gaze fear expressions in both Japanese and US Caucasian participants when viewing other-culture faces, and the relative increase in activation to averted- versus direct-gaze fear expressions in both cultural groups when viewing same-culture faces. This general pattern was also apparent when we examined activation within the anatomically defined region of bilateral amygdalae. Thus, this analysis replicates Hadjikhani *et al.*'s (2008) finding for greater averted- versus direct-gaze fear activation in US Caucasian participants viewing same-culture fear faces. For Japanese participants, however, no differences were found in processing averted- and direct-gaze same-culture fear faces in the amygdala. Given evidence for differences in neural activation that favor direct- versus averted-gaze in Japanese participants and stimuli, it may be that the differences found here were attenuated for Japanese participants due to the cultural meaning applied to direct gaze in Japanese culture. Direct eye gaze could have been construed as a threatening social cue when viewed in the context of a fear expression. Notably, both Japanese and US Caucasian participants showed similar amygdala responses to other-culture faces, with greater responsivity to direct- relative to averted-gaze fear faces. This latter effect is consistent with evidence for more amygdala activation in response to direct- relative to averted-gaze displays when viewing other-race faces (Richeson *et al.*, 2008).

There were also a number of regions related to face and eye gaze processing activated by the main effect of stimulus culture, including bilateral fusiform gyri, bilateral inferior temporal gyri, and bilateral angular gyri. Physiognomic differences in prototypical race appearance, such as eye size (see Zebrowitz, 1997) and brow height (Keating, Mazur, and Segall, 1977), could arguably be a source of such variation; however, our dependent variable of interest was computed as the direct comparison of direct and averted eye gaze on otherwise identical faces and expressions, thereby ruling out such explanations. The differences in activation necessarily reflect different processing of gaze behavior in the context of fear faces across the two cultures. Specifically, all participants showed greater activation to direct- relative to averted-gaze when displayed on Japanese faces, whereas the opposite was true for US Caucasian faces. This finding suggests that both Japanese and US Caucasian participants appear to share a common understanding of the distinct cultural meanings associated with gaze behavior and thereby process gaze in a similar manner. In this case, participants from both cultural groups showed more activation to incongruous eye gaze behaviors, based on what is generally considered most culturally appropriate. This is a unique finding suggesting that social cues related to culture may be transmitted and processed consistently across observers from different cultures.

The current investigation showed only one significant effect of gaze direction on the processing of fear expressions as a function of culture of participant, in the left angular gyrus. Given the known role of the angular gyrus/intraparietal sulcus in spatial orienting and gaze perception (Hoffman and Haxby, 2000; Sato *et al.*, 2008), this finding may represent a fundamental difference in gaze perception for Japanese and US Caucasian individuals—particularly in the context of processing fear. Inspection of the means revealed that this effect was largely driven by greater responses to direct- relative to averted-gaze in Japanese participants and to averted- relative to direct-gaze in US Caucasian participants. Given the cultural differences in display rules associated with gaze behavior, this finding may reflect a different role for direct versus averted gaze in these cultural groups. Given that this was not an *a priori* region of interest, however and that the whole-brain analysis yielded just this one relatively small cluster of activation showing this pattern, this finding must be taken with caution and warrants future corroboration.

The activations reported here show considerable overlap and consistency with regions previously reported (Table 1). The current work extends previous findings by demonstrating a robust intracultural effect within these regions for the role of gaze in fear perception. Of particular interest was the finding that amygdala responses to threat-gaze pairings varied as a function of whether participants viewed same- versus other-culture faces. This finding may help inform current inconsistencies reported across studies for role of gaze on fear processing at the neural level, with some work showing greater amygdala responses to ambiguous threat-gaze pairs (i.e. Whalen *et al.*, 2001; Adams *et al.*, 2003) and other work showing greater amygdala responses to clear threat-gaze pairs (Sato *et al.*, 2004; Hadjikhani *et al.*, 2008). In the current study the pattern of these responses cannot be attributed simply to a particular task or stimulus feature, and thus although the current work does not resolve this issue, the findings reported here are uniquely informative to ongoing research efforts examining this issue.

These findings also contribute to basic emotion theory. Recall that the *specific affect program* (Elfenbein and Ambady, 2003) highlights subtle culturally driven variation in expressive output as well as perceptual attunements to such variation. The current work suggests that culture heightens attunement to subtle, universally relevant aspects of expressions as well, in this case the mere millimeter shifts of irises and pupils that constitute changes in gaze direction. Recent work examining the integration of gaze in threat perception by women at different points along the menstrual cycle offers similar insight (see Conway *et al.*, 2007). This work found that women high in progesterone perceived fear and disgust expressions as more intense when coupled with averted relative to direct gaze, whereas those low in progesterone showed the opposite pattern. Given that both fear and

disgust signal the presence of an external contagion or threat in the environment, gaze is ecologically relevant to detecting its source. Thus, they argued that because pregnancy is also marked by high progesterone, the greater integration of averted gaze in the perception of fear and disgust in this study was likely due to an enhanced attunement triggered by increased threat vigilance. Continued inquiry into intrapersonal influences such as those found by Conway *et al.*, and cross-cultural influences such as those revealed by the present work, on compound threat cue processing is likely to yield important new insights into the perception of what are otherwise often regarded as obligatory responses to threat displays.

In sum, the dependent variable of interest employed in this examination represented a contrast between direct- and averted-gaze on otherwise identical faces posing identical expressions. Thus, every face and corresponding expression served as its own control. The neural differences we found were due to responses to the few millimeter shifts in pupils and irises that represent changes in gaze direction. Demonstrating any differences with such a small manipulation underscores just how powerful a social cue gaze is, despite being physically subtle. Gaze also holds different meanings cross-culturally and holds different meanings when conveyed by same- versus other-culture group members. That we found pronounced cultural variation in the influence of gaze on the neural processing of fear expressions highlights the extent to which both culture and gaze meaningfully influence what are often assumed to be obligatory neural responses to threat (see also Chiao *et al.*, 2008). Taken together, these findings suggest that we must consider how various social cues are processed in combination with one another for our understanding of the processing of each type of cue to be fully realized. Moreover, these findings underscore how cross-cultural examination is likely to advance a basic understanding of the mental and neural operations underlying social and emotional perception.
